

Prim's algorithm

Goal: to find min spanning tree of a graph

Idea: "grow the tree"

Algorithm: V = vertices of graph
 S = vertices of growing tree
 T = edges of growing tree

Initial step
I) Pick smallest edge
 $S = \{a, b\}$
 $T = \{ \text{edge } a-b \}$

II)

$S = \{a, b, d\}$

$T = \{ \text{a-b}, \text{a-d} \}$

out of edges

b-c	40
b-d	17
a-d	10
a-e	15

Picked a-d 10

III)

Repeat step II until $V - S = \emptyset$

Complexity

→ At each step, add vertex

→ so need $|V|$ iterations

In each iteration, have to pick

least edge among at most $|E|$ edges

→ so $|E|$

so $O(|V| |E|)$

$V = \text{vertices of } G$

$E = \text{edges of } G$

Implementation

Use "priority queue" to

efficiently pick smallest edge

- what is a priority queue?

- how to implement it?
